

# Functions in Python → Built in Functions

In math, a function is a relationship that maps inputs to outputs. Similarly, in Python or in any programming language we have functions. It is a self-contained block of code that takes inputs and produces outputs.

$$x, y \quad z = x + y = 4 + 2 = 6$$

Handwritten annotations: '4' under x, '2' under y.

## Why Use Functions?

1. **ABSTRACTION**: Functions hide complexity. You don't need to know how `len()` works internally, you just use it. When you create functions, you're building a vocabulary for your code with descriptive names instead of confusing statement sequences. `len()` → length of a sequence
2. **ENCAPSULATION**: Functions create their own namespace. Variables inside a function stay inside and no accidental interference occurs with the rest of your code.
3. **Modularity**: You organize your code in functions or modules and use it whenever required.
4. **REUSABILITY**: Without functions, you will copy-paste code everywhere. But with functions, change once and benefit everywhere.  
This is the DRY principle: Don't Repeat Yourself!
5. **MAINTAINABILITY**: Functions make code easier to understand, debug, and enhance. You can test each piece independently and document clearly.
6. **TESTABILITY**: Functions with clear inputs and outputs are easy to test. You can verify each function works correctly before combining them.

`Greeter()` :  
var → Inside a function
